APPENDIX C
HYDROGEOLOGICAL CALCULATIONS

This page intentionally left blank

APPENDIX C

HYDROGEOLOGICAL CALCULATIONS

1.0 INTRODUCTION

This Appendix provides backup for hydrogeological evaluations presented in the report, with both regional and local groundwater flow patterns presented. Overall, the regional groundwater flow is to the south southeast. The effects of groundwater withdrawal on both the regional and local groundwater flow patterns are illustrated through the construction of several maps depicting the magnitude and areal extent of changes in groundwater elevations caused by the pumping of public water supply wells located south of Hempstead Turnpike. The data used to construct these maps were obtained either during the two rounds of manual groundwater measurements (regional maps) or as recorded by electronic transducers placed in selected wells (local maps).

The withdrawal of groundwater by supply wells lowers the groundwater elevation in the vicinity of the wells. When the pumps are on, the groundwater elevations decrease, and when the pumps are turned off, the groundwater elevations rise back towards their natural (or “ambient”) conditions. The degree or magnitude of groundwater lowering and the areal expanse within which the lowering occurs is related to the hydraulic properties of the aquifer materials and the pumping rate of the supply well or wells; the greater the pumping rate, the greater the effects on groundwater elevation. Because groundwater flows from areas of higher groundwater elevation to areas of lower elevation, the pumping of the supply wells create local “sinks” into which groundwater can flow into and be drawn from any direction, including directions that are different than those delineated by the regional groundwater flow maps.

Area-wide groundwater levels in monitoring wells have been measured through the use of transducers, which are battery-powered instruments that are placed in the well and periodically record both time and water level. By recording the water levels at 5-minute intervals, very accurate graphs can be constructed that chart the groundwater levels in the well throughout a single day and throughout an entire pumping season (spring through fall).

2.0 REGIONAL GROUNDWATER FLOW CONDITIONS

Two rounds of groundwater elevation measurements were performed during 2018. The rounds were collected in July 2018 and October 2018. The depth-to-water measurements that were manually collected at each well were converted to elevations above mean sea level, which are subsequently used to interpret groundwater flow directions. Regional isocontour maps (isocontours are lines connecting locations of equal groundwater elevation) were developed for the two subsurface depth intervals of 500 to 700 feet below ground surface (bgs) and greater than 700 feet bgs. These two depth intervals contain the majority of the off-property mass of VOCs. In addition, there are insufficient monitoring wells screened in the 0 to 300 feet bgs and 300 to 500 feet bgs depth intervals near and south of Hempstead Turnpike (0 and 8, respectively), and therefore isocontour maps were not developed for the two shallower depth intervals.

The 500 to 700 feet bgs and greater than 700 feet bgs isocontour maps for July 2018 are included in the report as Figures 3-9 and 3-10 and Figures C-1 and C-3, and the maps for October 2018 are included in Figures 3-11 and 3-12 and Figures C-2 and C-4.

There are two seasonal differences in the water levels. One difference is the groundwater elevation at individual locations varies, which is due to either seasonal fluctuation or changes in groundwater withdrawal rates by the supply wells. The second difference is the change in the hydraulic gradient, as determined by the groundwater elevation between two points. The hydraulic gradient gets steeper as the contour lines become closer together on the map. The change in hydraulic gradient is primarily caused by the groundwater withdrawal by the supply wells.

There are also differences in the water levels within each season, including the changes in groundwater elevation and hydraulic gradient discussed above. These changes are primarily due to differences in the hydraulic properties of the various aquifer materials that consist of fine- to coarse-grained sands and gravel but also contain varying amounts of silt and clay. The hydraulic conductivity of the aquifer layers (or the “ease” with which groundwater flows through the material) varies with the grain size of the sands and the amount of finer-grained material that may retard the flow rate.

The interpreted groundwater flow directions are illustrated by blue arrows on the contour maps. Groundwater flow direction is perpendicular to the isocontour lines. On a regional scale, the groundwater south of Hempstead Turnpike consistently flows in a south to southeast direction. These maps are considered regional flow interpretations that define the overall, area-wide groundwater flow directions, but do not define smaller-scale variations in groundwater flow due to more localized changes in groundwater elevations or aquifer properties. Note that the effects of the groundwater pumping by the supply wells are not apparent on these maps, other than the lowering of the groundwater elevations through the summer, particularly in the monitoring wells located closest to the supply wells.

Evaluating the Effects of Well Pumping on Regional Groundwater Flow Patterns

To evaluate the effects of well pumping on groundwater flow patterns, Figures 3-13 and 3-14 were derived from the regional groundwater flow maps by contouring the drawdown (or decrease) in groundwater elevations between the July 2018 and October 2018 measuring rounds. This map illustrates the seasonal change in groundwater elevations south of Hempstead Turnpike. The most notable features of this map are the two regional sinks, or areas of greater seasonal drawdown. These sinks are interpreted to represent zones of groundwater capture or influence. Groundwater will either naturally flow or be drawn into these sinks through groundwater pumping, and subsequently be physically removed from the aquifer by the supply wells. The large sink to the south is created by the combined pumping of the SFWD 3-1, 6-1, and 6-2 and the NYAW -3S and -4S supply wells, and the smaller sink to the northeast is created by the pumping of the LWD-13 supply well.

Based on the available data, the two groundwater sinks are not interconnected, but are distinct and separate hydraulic basins. Under this interpretation, groundwater flowing into the southern sink (either induced by pumping or under regional flow) will be removed from the aquifer and not continue south. However, this interpretation is highly constrained by the uncertainty introduced by the large periodic (even daily) fluctuations in groundwater levels that were detected by the transducers and illustrated in Charts C-1 to C-4. Because the manual groundwater level measurements are not truly synoptic (taken at exactly the same time), the measurements for some wells may represent “pump off” conditions (higher water elevation), while the elevations in other wells may represent “pump on” conditions (lower elevation conditions). Thus, these regional flow interpretations based on groundwater elevation are potentially (or very likely) a mix of pumping and non-pumping measurements that are not representative of any particular condition that actually exists during the well pumping cycles. These measurements are not likely to highly impact regional flow interpretations, but they cannot be used to delineate the localized flow conditions that are created by the cyclic pumping of the different supply wells.

3.0 LOCALIZED GROUNDWATER FLOW CONDITIONS

Charts C-1 through C-4 illustrate the groundwater elevations recorded at five-minute intervals in six monitoring wells located within the project area from April 2018 through September 2018. These charts reflect short-term and long-term fluctuations in elevation that occurred from spring through fall as the demands from the different supply wells varied throughout the seasons. The charts are annotated with the Navy’s interpretation of the well(s) operating during the recorded intervals, but it is important to understand that these interpretations partly rely on general usage information provided by the water suppliers. The actual pumping histories (principally “on” or “off”) of the wells during the recording period are not known.

Chart C-1 illustrates the groundwater elevations in late April 2018, when regional groundwater levels are typically at their maximums. This chart shows an increase in pumping influence over the same period in 2017. This timeframe is interpreted to reflect the conditions attributable to the regular pumping of wells NYAW-3S and NYAW-4S and the periodic pumping of wells SFWD 3-1, SFWD 6-1, and SFWD 6-2. The cyclic pumping creates corresponding short-term changes in groundwater elevations of over three feet. The changes attributable to the individual wells are interpretative, and are based solely on the assumption that the greatest changes in water levels will occur in the monitoring wells that are located closest to the pumping well. For example, monitoring well BPOW 5-3 is located closest to supply well SFWD 3-1, so the largest variations recorded for BPOW 5-3 are believed to be caused by the pumping of SFWD 3-1. Chart C-1 also contains and reflects the period of maximum groundwater elevation that was observed during the 2018 recording season; this yearly maximum occurred on April 26 and is highlighted by the vertical red bar.

Chart C-2 illustrates the groundwater elevations from May into June 2018, when groundwater demand increases, especially during relatively short-lived “hot spells.” The periodic pumping of SFWD supply wells 3-1, 6-1, and 6-2 and NYAW-3S and 4S are apparent on this chart. The cyclic pumping creates corresponding short-term changes in groundwater elevations of up to two feet during this period.

Charts C-3 and C-4 illustrate the groundwater elevations throughout the summer, the months of July 2018 through early September 2018. These months typically represent the period of heaviest groundwater demand, and reflect both the near-continuous usage of primary supply wells and the frequent on-and-off cycling of seasonal supply wells. Note that the combined pumping of the wells can create daily fluctuations in the local groundwater elevations that are greater than 2 feet in magnitude. Chart C-4 also contains and reflects the time of minimum groundwater elevation that was observed during the 2018 recording season; this yearly minimum occurred on September 5 and is highlighted by the vertical red bar.

Evaluating the Effects of Well Pumping on Local Groundwater Flow Patterns

Figures C-5 to C-7 are constructed from groundwater elevations recorded by the transducers. The transducers are synchronized and record the time that the measurements are taken. Contour maps representing synoptic “snapshots” of groundwater elevations can be constructed, which eliminates the uncertainty that is introduced by the cyclic fluctuations in groundwater levels caused by the pumping of the supply wells. Every well does not have a transducer, this limits the number of wells that can be analyzed on Figures C-5 and C-7.

Figure C-5 is a groundwater elevation contour map as measured on April 26 at 4:30 a.m. (the yearly maximum denoted by the red bar on Chart C-1). Groundwater generally flows to the south and southeast, which is consistent with the directions illustrated by the regional flow maps. A subtle bending or deflection of the contours is detected in the vicinity of the NYAW -3S and -4S supply wells, which is interpreted to reflect the pumping of these wells.

Figure C-6 is a groundwater elevation contour map as measured on September 5 at 6:30 a.m. (the yearly minimum denoted by the red bar on Chart C-4, during a time of the day when all supply wells are apparently pumping, and during the time that represents the maximum drawdown recorded during the entire season). Here, the overall direction of groundwater flow is also to the south but is converging from the northwest and northeast into an interpreted groundwater sink.

Figure C-7 represents the total drawdown (decrease) in synoptic groundwater elevations as measured by the transducers on April 26, 2018 and September 5, 2018 and is similar to the Figures C-8 and C-9 that were constructed for the regional flow map. Figure C-7 differs from Figures C-8 and C-9 in that only one large groundwater sink can be interpreted. It is important to note that although the synoptic data removes the uncertainty caused by fluctuating groundwater levels, a different uncertainty is introduced by the absence of elevation data for monitoring wells RE129D1, RE129D2, RE127D1, RE127D2, BPOW 3-2, BPOW 2-3, BPOW 4-1R, BPOW 4-2R and BPOW 6-1, 6-2, 6-3, 6-5, and 6-6. The inability to depict the two distinct sinks that were interpreted with the regional maps is due to the absence of measurements at these locations using the synoptic data.

4.0 USGS Groundwater Flow Model

The USGS has completed a groundwater flow model to simulate the zones of groundwater contribution to the supply wells discussed in this report (USGS, 2018). Currently the USGS model and the interpretations made with the 2018 empirical data appear to agree on the directions of groundwater flow and the creation and location of groundwater sinks. The USGS states that under current conditions, no particles from the TCE plume are removed by the SFWD wells. However, the USGS also discusses the uncertainties associated with their simulation model, and how differences in their estimates of the aquifer's physical parameters or changes in the current well usage pattern and pumping rates can affect or change their interpretation.

5.0 VOC MIGRATION RATES

Groundwater velocity rates (and the associated VOC plume advection rates) are estimated using hydraulic head (groundwater elevation) data collected from Northrop Grumman and NWIRP wells in 2018 and values of aquifer hydraulic conductivities from recent field studies. Plume migration rates may vary from the groundwater flow rates due to non-uniform flow pathways, dilution, area-wide pumping by supply wells, and targeted VOC mass removal from groundwater by remedial wells.

The migration of VOCs is dependent on several factors. On a microscopic scale, groundwater (and groundwater contaminants) moves through open pore spaces in saturated aquifer sediments comprised of gravel, sand, silt, and clay in response to elevation and/or pressure-head differences (i.e., hydraulic gradients) between two locations. Over large areas, the "average linear velocity" provides an estimate of how long it would take groundwater (and a non-reactive chemical) to move in an aquifer. Average linear velocity is computed using hydraulic conductivity, hydraulic gradient (determined from the groundwater contour maps), and effective porosity (i.e., specific yield).

Average linear velocity calculations are summarized in Table C-1. The effective porosity and hydraulic conductivity parameters are based on pumping test data collected from trials at Bethpage Water District Well 6-2 (Tetra Tech, 2014 and Resolution, 2016) and GM38 Area Hotspot Treatment System (OU2) (Tetra Tech, 2010). Hydraulic gradients are calculated from the regional groundwater flow maps presented in Figures C-1 through C-4.

The estimated groundwater velocities represent the project area south of Hempstead Turnpike and are calculated only for the 500 to 700 feet bgs and the greater than 700 feet bgs subsurface intervals. There is insufficient groundwater elevation data to calculate the gradients for the shallower intervals in this portion of the plume.

Because the hydraulic gradient varies throughout the year in response to seasonal fluctuation and groundwater pumping, two sets of calculations were performed for each of the two subsurface intervals. One calculation was performed for the July 2018 conditions and the other calculation was performed for the October 2018 conditions. The largest difference in average linear velocities was between the subsurface

intervals, while a slightly smaller seasonal difference was noted within each interval. The velocities calculated for the 500 to 700 feet bgs interval ranged from 212 feet/year to 435 feet/year in the spring and 224 feet/year to 341 feet/year in the fall; the velocities calculated for the greater than 700 feet bgs interval ranged from 346 feet/year to 418 feet/year in the spring and 344 feet/year to 404 feet/year in the fall. The overall average linear velocity for the aquifer, combining both depth intervals and seasons, was 320 feet/year.

6.0 POTENTIAL FUTURE IMPACTS TO DRINKING WATER FACILITIES

The main body of this report discusses well fields currently impacted by VOCs associated with the former Northrop Grumman and NWIRP facilities, and also identifies those well fields equipped with treatment systems to remove the VOCs migrating or potentially migrating from the former Northrop Grumman and NWIRP facilities. This appendix discusses the potential future migration of the groundwater plume relative to the groundwater patterns that have been discussed.

This discussion focuses on the southern portion of the groundwater plume, or that area located generally south of Hempstead Turnpike, as impacts to wells located north of this area have already been addressed. The discussion also focuses on the 500 to 700 feet bgs and the greater than 700 feet bgs depth intervals, because these deeper intervals correspond with the zones of maximum water withdrawal in the southern area, and because to the south of Hempstead Turnpike there are an insufficient number of shallower data points to confidently contour.

The public water supplies that are currently not impacted by the groundwater plume but are relatively close to the downgradient edge of the plume are South Farmingdale Water District Well 1-4, and South Farmingdale Water District Well Nos. 6-1 and 6-2. These wells do not currently have treatment systems in place, but outpost monitoring wells were installed to provide early indication of when treatment might be necessary for each of these well fields. The outpost monitoring wells are placed at depths associated with the supply wells and are located between the plumes and the supply wells such that VOCs would have to flow through outpost monitoring wells several years prior to entering the public water supply wells. This advance notice of VOCs provides early warning that an action is needed.

As the various groundwater plumes move from the source areas and migrate to the south and southeast, they are undergoing dilution, and are affected by pumping and VOC mass removal systems that serve to weaken them. In addition, portions of these plumes are being intercepted by water supply wells with treatment that further hinder migration. Each of these actions reduces the intensity of the plumes. The result is that many of the water districts to the south may never be impacted, or if they are impacted, the effects from the plumes may not be seen for decades.

The effects on groundwater flow rates and directions created by the pumping of the supply wells located south of Hempstead Turnpike have been discussed. Figures 4-2 and 4-3 reproduce Figures 3-13 and 3-14 (the location of groundwater sinks as constructed from the regional groundwater flow maps), except that

the downgradient location and extent of the TCE plumes have been added and superimposed over the groundwater elevation contours.

Under the interpretation depicted in Figures 4-2 and 4-3, the TCE plume extends into the large, united sink created by the pumping of SFWD 3-1 and NYAW -3S and -4S (which have treatment systems) and SFWD 6-1 and 6-2 (which do not have treatment systems). Because the greatest drawdown within the aquifer is recorded in the vicinity of the SFWD 6-1 and 6-2 wells, the potential exists for groundwater within the sink (including some portion of the TCE plume) to be withdrawn by these wells.

For the SFWD Plant 6, and based on site-specific hydrogeological calculations presented in Table C-1, groundwater could travel from the currently depicted edge of the OU2 plume to South Farmingdale Water District Wells 6-1 and 6-2 (a distance of about 2,500 feet) in approximately 6 years. As discussed however, plume migration would be hindered (and potentially prevented) by the operation of South Farmingdale Water District Plant 3 and New York American Water (both with VOC treatment), and it is unclear whether the plume would ever reach South Farmingdale Water District Wells 6-1 and 6-2. Because of the uncertainty with the groundwater flow interpretations and the uncertainty inherent in groundwater velocity calculations, outpost monitoring wells are in place to provide five-year advance notice so that installation of treatment at these supply wells can be initiated, if necessary.

For Massapequa Water District Wells 4 and 5, it is unclear whether the VOC plume could reach these wells due to the intervening groundwater sink caused by the pumping of the supply wells discussed above. One uncertainty concerns whether the pumping of the MWD wells contribute to and become part of the large groundwater sink, or are too distant to have an effect. There are insufficient empirical data to confirm either interpretation, and this well field is not part of the USGS flow simulation model. In addition, operation of the RE108 Area Hotspot Treatment System would be expected to further limit mass flow of VOCs toward the South Farmingdale Water Districts and New York American Water District Plants, and thereby further limit mass flow toward Massapequa Water District.
